We interpret cooperative scattering by a collection of cold atoms as a multiple scattering process. Starting from microscopic equations describing the response of $N$ atoms to a probe light beam, we represent the total scattered field as an infinite series of multiple scattering events. As an application of the method, we obtain analytical expressions of the coherent intensity in the double scattering approximation for Gaussian density profiles. In particular, we quantify the contributions of coherent backward and forward scattering.

1. Introduction

Multiple scattering of light in disordered media has been investigated since a long time using different approaches [1–3]. Some of them used coupled dipoles methods to describe light scattering by dielectric particles, [4] while other approaches interpret multiple scattering as a random walk of particle-like photons where interference is neglected. This random walk is described by a radiative transfer equation [5–7] which has been used for decades in astrophysics, where the diffusive behavior is considered as a good description of the light propagation. However, this approach must be corrected when the scattered light wave emerges from the medium in the backward direction. In this case, constructive interferences arise and must be taken into account in order to explain the enhancement of the backscattered intensity with respect to the classical prediction [8–11]. This coherent back-scattering (CBS) has been observed for light waves in a variety of media such as powder suspensions, biological tissues or Saturn’s rings as well as for laser-cooled atomic gases [12–14]. The latter systems provide an opportunity to observe cooperative effects in the light scattering due to the absence of Doppler broadening.

Recently, a microscopic model of cooperative scattering by cold atoms was proposed [15–19], which accounts for the interference effects. Signatures of cooperativity have been observed in the reduction of the radiation pressure force exerted on the center-of-mass of the atomic cloud [20, 21]. The microscopic model provides an exact description of the scattering of a probe light beam by $N$ atoms, i.e., taking into account interferences. It assumes the incident light beam to be weak enough to neglect nonlinear effects, but naturally embeds the multiple scattering process of the incoming photons bouncing among the atoms, since the single-atom response is proportional to the sum of the incident field and the field scattered by the other atoms.

The aim of the present paper is to characterize the multiple scattering nature of cooperative scattering, describing it not from the point of view of the atoms, but of the scattered field. Under this view, cooperative scattering appears as a sequence of multiple scattering events where the emitted field is expressed as the sum of successively scattered fields. This approach is of particular importance for two reasons. Firstly, scattering in optically dilute systems is very well described by a few scattering events. The number of these events necessary to reconstruct the solution is directly connected to the convergence of the multiple scattering series. Secondly, it happens that the multiple scattering expansion diverges in the optically dense regime. This suggests that the interpretation of multiple scattering as photons wandering from one atom to another one starts to be incomplete. In such a regime, we can only talk about global scattering by the entire cloud, and we lose track of the light propagating in the cloud at different orders of scattering. As a consequence, the scattered field seen by each atom can not be obtained as the coherent sum over all the light trajectories, but it must result from a global approach, determining or the single-atom response to the total scattered field [22] or the eigenmodes of the system [23].

Let us outline that we treat the light scattering ab
The steady-state problem of Eq. (1) boils down to a linear one for the complex vectors $b_j$ with spatial components $b_j^\alpha$:

$$b_j = \frac{1}{\Delta + i\gamma/2} \left[ \frac{d}{\hbar} E_{in}(r_j) - i\frac{\gamma}{2} \sum_{m \neq j} G(r_j - r_m) \cdot b_m \right].$$

(4)

Giving the atomic positions $r_j$ and incident field $E_{in}(r_j)$, it can be solved numerically by inverting a $3N \times 3N$ symmetric matrix.

The scattered field at a position $r$ is derived from $b_j$ using the microscopic Maxwell equations for sources of polarization $P(r) = -d \sum_j b_j \delta(r - r_j)$. The result, as demonstrated in the Appendix A reads:

$$E_{sca}(r) = -i \frac{d}{6\pi\epsilon_0} \sum_{m=1}^N G(r - r_m) \cdot b_m.$$  

(5)

The scattered field $E_{sca}(r_j)$ at the atomic position $r_j$ has a divergent contribution in the term $m=j$ of the sum in Eq. (5). This is a well-known problem of the self-field, i.e., the field generated by the atom acting on the atom itself. Usually, in multiple scattering theories this problem is circumvented by introducing a cut-off length of the order of the size of the real physical scatterer [24]. However, in the present approach the self-field does not play any role. In fact, calling $E_{self}(r_j)$ the self-field of the atom $j$, Eq. (5) turns into:

$$E_{sca}(r_j) = E_{self}(r_j) - i \frac{d}{6\pi\epsilon_0} \sum_{m \neq j} G(r_j - r_m) \cdot b_m.$$  

(6)

Combining Eqs. (4) and (6), one can obtain:

$$b_j = \frac{d}{\hbar(\Delta + i\gamma/2)} \left[ E_{in}(r_j) + \bar{E}(r_j) \right],$$

(7)

where $\bar{E}(r_j) = E_{sca}(r_j) - E_{self}(r_j)$ is the electric field acting on the $j$th atom without the self-field contribution. $\bar{E}(r_j)$ is introduced to describe the field at the atomic positions and avoid the divergence problem present in (6). The electric dipole moment of each atom $p_j = -d b_j$ is directly proportional to the sum of the incident field and the one scattered by all other atoms, as assumed in the cooperative scattering description [4].

3. **The multiple scattering series**

In the microscopic approach of cooperative scattering presented in Sec. 2 the radiation field is determined from the knowledge of the individual atomic responses $b_j$, which are themselves derived from the linear problem Eq. (4). On the contrary, the multiple scattering approach is based on a recursive set of equations for the sole radiation field. It is obtained by inserting Eq. (4) back into Eq. (6), leading to an implicit equation for the scattered field $\bar{E}(r_j)$ acting on the $j$th atom:

$$\bar{E}(r_j) = \kappa(\delta) \sum_{m \neq j} G(r_j - r_m) \cdot [E_{in}(r_m) + \bar{E}(r_m)],$$

(8)
where $\kappa(\delta) = 1/(2i\delta - 1)$ and $\delta = \Delta/\gamma$. Introducing the total field $\vec{E}_{\text{tot}}(\mathbf{r}_j) = \vec{E}_{\text{in}}(\mathbf{r}_j) + \vec{E}(\mathbf{r}_j)$, the above equation can also be written in a matrix form

$$\vec{E}_{\text{tot}} = (I - \mathcal{G})^{-1} \vec{E}_{\text{in}}, \quad (9)$$

where $\vec{E}_{\text{tot}}$ and $\vec{E}_{\text{in}}$ are vectors containing the 3N components of the effective electric field acting on the $j$th atom (without the self-field contribution) and the incident field, respectively; $I$ is the $3N \times 3N$ unit matrix, and $\mathcal{G} = \kappa(\delta)\mathcal{G}$ is a $3N \times 3N$ matrix containing the Green’s function $G_{jm} = G(\mathbf{r}_j - \mathbf{r}_m)$ whose component are given by Eq. (2).

The multiple scattering approach consists in solving Eq. (9) by iteration. Introducing the scattered field $\vec{E}^{(n)}$ after $n$ scattering events, the following recurrence relation is obtained from Eq. (9):

$$\vec{E}^{(n)}(\mathbf{r}_j) = \kappa(\delta) \sum_{m \neq j} G(\mathbf{r}_j - \mathbf{r}_m) : \vec{E}^{(n-1)}(\mathbf{r}_m), \quad (10)$$

where $n = 1, 2, \ldots$ and the incident field $\vec{E}^{(0)}(\mathbf{r}_j) = \vec{E}_{\text{in}}(\mathbf{r}_j)$ plays the role of the seed. The total scattered field $\vec{E}(\mathbf{r}_j)$ corresponds to the infinite sum of all scattered fields

$$\vec{E}(\mathbf{r}_j) = \sum_{n=1}^{\infty} \vec{E}^{(n)}(\mathbf{r}_j), \quad (11)$$

provided the series is converging. The effective field felt by the scatterer at $\mathbf{r}_j$ consists of the incident wave $\vec{E}_{\text{in}}(\mathbf{r}_j)$ and the wave scattered from the other atoms in the cloud (except the self field of the atom at $\mathbf{r}_j$) given by Eq. (11) and resulting from an increasing number of scattering events of the incident field. Eq. (9) can be extended as a series:

$$\vec{E}_{\text{tot}}(\mathbf{r}_j) = \vec{E}_{\text{in}}(\mathbf{r}_j) + \kappa(\delta) \sum_{m \neq j} G(\mathbf{r}_j - \mathbf{r}_m) \vec{E}_{\text{in}}(\mathbf{r}_m)$$

$$+ \kappa^2(\delta) \sum_{m \neq j} G(\mathbf{r}_j - \mathbf{r}_m) \sum_{l \neq m} G(\mathbf{r}_m - \mathbf{r}_l) \vec{E}_{\text{in}}(\mathbf{r}_l)$$

$$+ \ldots \quad (12)$$

The infinite series (12) converges only if all eigenvalues of $\mathcal{G}$ have their modulus less than unity [27]. When this condition is satisfied, the multiple scattering expansion can be used to calculate the radiated field.

Note that the convergence of the series (12) or of the sum (12) is not tied to the existence of a solution for the field. Indeed Eq. (9) always admits a solution, whereas the linear operator $\mathcal{G}$ of the recurrence Eq. (11) may admit eigenvalues of modulus larger than unity, in which case Eq. (11) does not converge. In that case each scattering order radiates more light than the previous one, and the multiple scattering expansion diverges. In order to illustrate this point, the electric field profile inside a Gaussian cloud $\vec{E}^{(n)}(\mathbf{r}) = \kappa(\delta) \sum_j G(\mathbf{r} - \mathbf{r}_j) \vec{E}^{(n-1)}(\mathbf{r}_j)$ and the far-field radiated power $P^{(n)} = (\varepsilon_0 c/2) \int |\vec{E}^{(n)}|^2 dS$ are plotted for different orders $n$ in Fig. 1 and 2 respectively. Both quantities have been obtained for two different optical thicknesses $b(\delta) = b_0/(1 + 4\delta^2)$, where $b_0 = 3N/(k^2\sigma^2)$ is the resonant optical thickness. The two simulations have been realized for $N = 500$ atoms with $b_0 = 5$, standard deviation $\sigma_R = 17.32/k$ and for two different detuning, $\delta = 4.5$ and $\delta = 0$, corresponding to $b(\delta) = 0.061$ and $b(\delta) = 5$, respectively. For the case of small optical thickness ($b(\delta) = 0.061$), the field decreases as the scattering order $n$ increases, and the series (11) converges. For the case of larger optical thickness ($b(\delta) = 5$), the presence of eigenvalues of modulus larger than unity makes the multiple scattering series diverge. Hence, in presence of above-unity eigenvalues of $\mathcal{G}$, the multiple scattering description loses its validity: for sufficiently dense media, due to the long-range interaction of the Green’s function, the build-up of the scattered radiation field cannot be seen as the sum of interactions involving an increasing number of atoms, and the local iteration of the scattering event described by Eq. (11) is no longer possible. Instead, the total scattered field is a result of a global interaction with the entire sample. Let us remark that the criterion of all eigenvalues having modulus below unity for the convergence of the series is in agreement with the results of Ref. [28]. A detailed study of the typical spectrum of the linear operator in (10) has been proposed in Ref. [29], yet it is important to mention that the spectrum exhibits strong fluctuations from one realization to another. Since the multiple scattering process corresponds to a geometric series, the radiated power grows or decreases as a power-law of the largest eigenvalue of the linear operator in Eq. (11) for large $n$.

Once obtained from Eq. (11) $\vec{E}(\mathbf{r}_j)$, using Eqs. (5) and (7) the scattered field in position $\mathbf{r} \neq \mathbf{r}_j$ is fully determined as:

$$\vec{E}_{\text{scat}}(\mathbf{r}) = \kappa(\delta) \sum_{j=1}^{N} \vec{G}(\mathbf{r} - \mathbf{r}_j) \cdot [\vec{E}_{\text{in}}(\mathbf{r}_j) + \vec{E}(\mathbf{r}_j)] \quad (13)$$

The multiple scattering nature of the field detected at $\mathbf{r}$ is evident from Eq. (13): the first term in the sum represents all the single scattering and the second term collects all the multiple scattering. The $\vec{E}(\mathbf{r}_j)$ term, which contains all scattering orders starting from the first (see Eq. (11)), yields the double and higher scattering orders in (13) after applying $\vec{G}$.

We point out that the solution for the scattered field (given by the infinite series of Eq. (11) and Eq. (13)) is fully equivalent to solving Eq. (11) for $\mathbf{b}_j$ and then calculating the field using Eq. (10). Eq. (10) can be solved exactly by numerical inversion of this linear problem. The only constraint we deal with is the limited number $N$ of scatterers that can be handled by the computer capacities. From the perspective of computing the scattered field, the microscopic approach has a clear advantage over the multiple scattering one, which requires the evaluation of an infinite sum. The numerical solution of the microscopic approach provides a solution valid for
For small optical thickness ($b(\delta) = 0.061$, red crosses), the scattered power decreases as the scattering order $n$ increases, whereas for larger optical thickness ($b(\delta) = 5$, blue dots), the power diverges. $P^{(n)}$ is in units of the independent-atom power $NP_1$, where $P_1 = (4\pi I_0/k^2)/(1 + 4\delta^2)$ and $I_0$ is the incident intensity.

Lastly, we emphasize that if the infinite sum in Eq. (11) converges, it gives the exact solution for the collective scattering problem given by Eqs. (4)-(6). To illustrate this point, we compare the intensity radiated up to the $n$th order $I^{(n)} = (\varepsilon_0 c/2)|\sum_{j=1}^{n} E^{(j)}|^2$ for $n = 1, 2, 3$, as well as the intensity $I_0$ provided by the dipole amplitudes $b_m$ derived from Eq. (4) and containing all the scattering orders. In particular, $I^{(1)}$ describes the single scattering only, $I^{(2)}$ the sum of single and double scattering, etc. For an optical thickness $b(\delta)$ equal to unity ($b_0 = 1, \delta = 0$), the convergence is relatively slow, but clearly visible in Fig 3. For optical thickness much smaller than unity, the convergence is very fast and the single-scattering physics contained in $E^{(1)}$ describes already very well the total scattered field (not shown here).

We note in Fig. 3 that the coupled dipole equation predicts a background radiation lower than $N$ times that of a single-atom. This suggests a reduction of the background radiation, in favor of the coherent forward radiation, under the effects of cooperativity. This effect will be the subject of a future dedicated study.

![Fig. 2. (Color online) Far-field power $P^{(n)} = (\varepsilon_0 c/2) \int |E^{(n)}|^2 dS$ radiated by the atomic cloud (measured on a spherical surface of radius $r \gg k$) vs. the scattering order $n$ for the same parameters as in Fig 1](image-url)
The intensity scattered by the dipoles, light): the single-atom intensity derived from Eq. (13). The intensity scattered by the dipoles, \( I_{\text{sc}} \) is replaced by \( \frac{\varepsilon b}{(\cos^2 \theta)} \) with on-resonance optical thickness \( \sigma \). The intensity is averaged over the azimuthal angle \( \phi \) vs the polar angle \( \theta \), where \( I_1 = \frac{I_0}{(k^2 r^2) (1 + 4 \delta^2)} \) and \( \delta = 0 \). Fig. 4 shows a zoom of the radiation vectorial nature of the light (linearly polarized light): the single-atom intensity \( I_1(1 + \cos^2 \theta) \) is plotted as a plain green line, where \( I_1 = I_0 / (k^2 r^2) (1 + 4 \delta^2) \). In the inset shows a zoom of the radiation theory, the three components \( b_1^2 / \lambda \) are replaced by a single value \( \beta \), the vectorial function \( G_{\alpha, \alpha'}(r) \) is substituted by the scalar Green’s function \( G(r) = \exp(ikr)/ikr \) and the decay constant \( \gamma \) is replaced by \( \Gamma = (3/2) \gamma \). Then, the scalar equivalent of Eq. (13) is

\[
E_{\text{sc}}(r) = \kappa(\delta) \sum_{j=1}^{N} G(|r - r_j|) [E_{\text{in}}(r_j) + \tilde{E}(r_j)].
\]

(19)

We approximate the multiple scattering field \( \tilde{E}(r_j) \) by its first contribution:

\[
\tilde{E}(r_j) \approx \kappa(\delta) \sum_{m \neq j} G(|r_j - r_m|) E_{\text{in}}(r_m),
\]

(20)

which is equivalent to considering single- and double-scattering events only:

\[
E_{\text{tot}}(r) = E_{\text{in}}(r) + \kappa(\delta) \sum_{j=1}^{N} G(|r - r_j|) E_{\text{in}}(r_j)
\]

\[
+ \kappa^2(\delta) \sum_{m=1}^{J} \sum_{j \neq m} G(|r - r_m|) G(|r_m - r_j|) E_{\text{in}}(r_j).
\]

(21)

The second term in Eq. (21) describes the single scattering of the incident wave by each atom in position \( r_j \), followed by its propagation towards \( r \). The third term corresponds to the double scattering, i.e. the photons are first scattered by the atoms in \( r_j \), then propagate to \( r_m \), where they are scattered again and reach position \( r \). As it can be observed in Fig. 3, the double-scattering is the first of the multiple scattering process that contributes to CBS. It results from the interference between the wave which is first scattered in \( r_j \) and then in \( r_m \), and the reciprocal path, when the wave is first scattered in \( r_m \) and then in \( r_j \). This effect can be captured by calculating the scattered field in the far-field limit, approximating the Green’s function as \( G(|r - r_j|) \approx \exp(ikr - i \kappa \cdot r_j)/(ikr) \):

\[
E_{\text{sc}}(r) = \kappa(\delta) \frac{\varepsilon b}{ikr} E_0 \sum_{j=1}^{N} e^{i(\kappa_0 - k) \cdot r_j}
\]

\[
+ \kappa^2(\delta) \frac{\varepsilon b}{ikr} E_0 \sum_{m=1}^{N} \sum_{j \neq m} G(|r_m - r_j|) e^{i(\kappa_0 - k) \cdot r_m},
\]

(22)

where we assume that the incident field is a plane-wave \( E_{\text{in}}(r) = E_0 \exp(i \kappa_0 \cdot r) \). Introducing the factor

\[
T_N(k, \kappa_0) = \frac{1}{N} \sum_{j=1}^{N} \sum_{j \neq m} G(|r_j - r_m|) e^{i(\kappa_0 - k) \cdot r_m},
\]

(23)

the scattered intensity up to the second scattering order can be written as:

\[
I_{\text{sc}}(r) = I_1 N^2 |S_N(k - \kappa_0) + \kappa(\delta) |T_N(k, \kappa_0)|^2, \quad (24)
\]

where \( I_1 = I_0 /[k^2 r^2 (1 + 4 \delta^2)] \) is the single-atom scattered intensity and \( I_0 \) is the intensity of the incident wave. Upon configuration averaging, the structure factor gives an incoherent contribution, \(|S_N(k - \kappa_0)|^2 = 1/N\), while the coherent contribution in the forward direction for large \( N \) can be written as a continuous integral:

\[
S_{\text{c}} = \frac{1}{N} \int dr \rho (r) \exp[i(\kappa - \kappa_0) \cdot r],
\]

(25)

where \( \rho(r) \) is the atomic density. \(|T_N|^2 \) yields an incoherent contribution plus two coherent contributions which, however, have different origins. Taking the square modulus of Eq. (23) and considering only equal pairs of atoms \((j, m)\) in \( T_N \) and \( T_N^* \), we obtain:

\[
|T_N(k, \kappa_0)|^2 \approx \frac{1}{N^2} \sum_{j=1}^{N} \sum_{j \neq m} \cos[(k + \kappa_0) \cdot (r_j - r_m)]^2.
\]

(26)

The first incoherent term emerges when the same pair of atoms is considered twice \((1/k^2 |r_j - r_m|^2 \text{ term in Eq. (20)}\), whereas the second term results from the pair \((j, m)\) crossed with its reciprocal path \((m, j)\) (cosine term). The latter is known as the CBS term [8].

4. Coherent Backward and Forward Scattering

As an application of the multiple scattering approach, we investigate coherent backscattering (CBS) and coherent forward scattering (CFS) from a collection of \( N \) atoms. For the sake of simplicity, we assume that the radiation waves are scalar, neglecting polarization and near-field effects. In the scalar radiation theory, the three components \( b_j^2 / \lambda \) are replaced by a single value \( \beta \), the vectorial function \( G_{\alpha, \alpha'}(r) \) is substituted by the scalar Green’s function \( G(r) = \exp(ikr)/ikr \) and the decay constant \( \gamma \) is replaced by \( \Gamma = (3/2) \gamma \). Then, the scalar equivalent of Eq. (13) is

\[
E_{\text{sc}}(r) = \kappa'(\delta) \sum_{j=1}^{N} G(|r - r_j|) [E_{\text{in}}(r_j) + \tilde{E}(r_j)].
\]

(19)

We approximate the multiple scattering field \( \tilde{E}(r_j) \) by its first contribution:

\[
\tilde{E}(r_j) \approx \kappa'(\delta) \sum_{m \neq j} G(|r_j - r_m|) E_{\text{in}}(r_m),
\]

(20)

which is equivalent to considering single- and double-scattering events only:

\[
E_{\text{tot}}(r) = E_{\text{in}}(r) + \kappa'(\delta) \sum_{j=1}^{N} G(|r - r_j|) E_{\text{in}}(r_j)
\]

\[
+ \kappa'^2(\delta) \sum_{m=1}^{J} \sum_{j \neq m} G(|r - r_m|) G(|r_m - r_j|) E_{\text{in}}(r_j).
\]

(21)
ward intensity due to the processes involving more than terms, corresponds to the first 'ladder' term and the second since it also yields a backward coherent radiation. In addition to the background. The theoretical curves (th) are realized for a Gaussian spherical cloud consisting of $N = 400$ atoms with resonant optical thickness $b_0 = 2N/(k\sigma R)^2 = 1$, standard deviation $\sigma_R \approx 28.3/k$, detuning $\delta = 1$ and averaged over 1000 realizations. The incoming field is unity $E_0 = 1$ and the radius of observation is $3 \cdot 10^3/k$. Scale is Logarithmic.

since it also yields a backward coherent radiation. In the diagrammatic approach, the first term in Eq. (26) corresponds to the first 'ladder' term and the second one to the 'most-crossed term' (24). Besides these pair terms, $T_N$ also gives a coherent contribution to the forward intensity due to the processes involving more than two atoms. This contribution in the continuous density limit can be written as:

$$T_\infty(k, k_0) = \frac{1}{N} \int d\mathbf{r}_1 \rho(\mathbf{r}_1) \int d\mathbf{r}_2 \rho(\mathbf{r}_2) \exp\left(\frac{i \mathbf{k} \cdot \mathbf{r}_1 - \mathbf{k}_0 \cdot \mathbf{r}_1}{i \mathbf{k} \cdot \mathbf{r}_1 - \mathbf{k}_0 \cdot \mathbf{r}_2}\right) \times e^{i(k_0 \cdot \mathbf{r}_1 - \mathbf{k} \cdot \mathbf{r}_2)}. \quad (27)$$

Collecting the different contributions, the scattered intensity up to the double scattering order reads:

$$I_{sca} = I_1 N \left\{1 + \frac{N}{1 + 4\delta^2} |T_N|_{\text{pair}}^2 + N|F|^2\right\}, \quad (28)$$

where $F = S_\infty + \kappa(\delta)T_\infty$. The first term is the isotropic incoherent contribution $NI_1$ of $N$ independent atoms. The second term enhances the previous incoherent term and also provides the CBS cone (second term in Eq. (26)). Finally, the third term in Eq. (28) contributes to the coherent forward emission as the sum of the single and double scattering contributions.

The CBS cone reveals itself upon averaging over the pair double scattering term (26). We first average over the direction of the vector $\mathbf{r}_j - \mathbf{r}_m$, assuming an atomic distribution with infinite boundaries, as for instance the Gaussian one which is easy to parametrize. Moreover, there is no need to know the details about the density of the cloud, since we deal with angular variables only. We note that although the procedure does not correspond to a rigorous configuration average, it allows for analytical results and compares well with numerical results obtained by configuration averages (see Fig. 4).

This first averaging results in (see Appendix B for details):

$$\langle |T_N|_{\text{pair}}^2 \rangle = \frac{1}{N^2} \sum_j \sum_{m \neq j} \frac{1}{k^2 r_{jm}^2} \times \left\{1 + \sin \left[\frac{2k r_{jm} \cos(\theta/2)}{2k r_{jm} \cos(\theta/2)}\right]\right\}, \quad (29)$$

where $\theta$ refers to the angle of $\mathbf{k}$ with respect to the direction of $k_0$. The average over the pair distance $r_{jm} = |\mathbf{r}_j - \mathbf{r}_m|$ is the next step, and the resulting backscattering enhancement depends on the atomic distribution. In the next section, we discuss the CBS for Gaussian spheres.

**Gaussian sphere density profile**

As discussed previously, our multiple scattering approach is valid for arbitrary geometries, including inhomogeneous media. Let us illustrate this on a Gaussian sphere of standard deviation $\sigma_R$, for which the contribution of double scattering to CBS enhancement reads (see Appendix C):

$$\langle |T_N(\theta)|^2 \rangle_{\text{pair}} = \frac{1}{2\sigma^2} \left\{1 + \sqrt{\pi} \operatorname{erf}\left[\frac{2\sigma \cos(\theta/2)}{\sqrt{2} \sigma \cos(\theta/2)}\right]\right\} = \frac{E(\theta)}{2\sigma^2} \quad (30)$$

with $\sigma = k\sigma_R$. $E(\theta)$ has a maximum enhancement of 2 (see Fig. 5) and an angular FWHM of $\Delta \theta = 2\sqrt{3}/\sigma \approx 0.55(\lambda/\sigma_R)$. 

---

**Fig. 4.** (Color online) Radiation profile $|E^{(n)}(\theta)|^2$ in the far-field limit for scattering orders $n = 1, 2$. The single-scattering order $E^{(1)}$ exhibits only a forward contribution (peaks pointing to the right) and a homogeneous background. The double-scattering contribution $E^{(2)}$ shows both forward and backward (CBS) patterns (peaks pointing to the left) in addition to the background. The theoretical curves (th) correspond to the first ‘ladder’ term and the second since it also yields a backward coherent radiation. Simulations realized for a Gaussian spherical cloud of on-resonant optical thickness $b_0 = 1$, $N = 200$ particles, scaled size $\sigma = 20$ and laser detuning $\delta = 0.5$. The intensity has been averaged over 1000 realizations.

**Fig. 5.** (Color online) Far-field scattered intensity vs. $\theta$ up to the $1^{st}$, $2^{nd}$ and $3^{rd}$ scattering order, i.e., $I^{(n)} = \langle |E^{(n)}(\theta)|^2 \rangle_{\text{sca}}$, in units of $NI_1$. The inset is a zoom of the backscattering region (linear scale). Simulations realized for a Gaussian spherical cloud of on-resonant optical thickness $b_0 = 1$, $N = 200$ particles, scaled size $\sigma = 20$ and laser detuning $\delta = 0.5$. The intensity has been averaged over 1000 realizations.
For a Gaussian sphere, the single-scattering forward contribution gives, (see Ref. [17], Eq. (25)),
\[ S_\infty(\theta) = \exp[-2\sigma^2 \sin^2(\theta/2)], \tag{31} \]
while the second-order forward contribution, in the limit of large spheres \( \sigma \gg 1 \), is:
\[ T_\infty(\theta) \approx \frac{N}{4\sigma^2} \exp[-4\sigma^2 \sin^2(\theta/4)]. \tag{32} \]
The exact expression and its derivation are given in Appendix E. The total scattered intensity for a Gaussian sphere, up to the second scattering order (see Eq. (28)), reads:
\[ I_{\text{scat}}(r) = I_1 N \left\{ 1 + \frac{b(\delta)}{4} E(\theta) + N|F(\theta)|^2 \right\}, \tag{33} \]
where the forward contribution is given by:
\[ F(\theta) = e^{-2\sigma^2 \sin^2(\theta/2)} - (1 + 2i\delta) \frac{b(\delta)}{8} e^{-4\sigma^2 \sin^2(\theta/4)}, \tag{34} \]
and \( b(\delta) = b_0/(1 + 4\delta^2) \) with \( b_0 = 2N/\sigma^2 \) being the resonant optical thickness for scalar light.

The background second-order scattering is observed to interfere destructively with the background first-order scattering in Fig. 2, leading to an overall reduction of the background radiation. This effect is already present in the mathematical expression of the forward contribution given by Eq. (33), which is expected to be the dominant term except for the backward direction.

**Coherent Back-Scattering.** — Our analysis is in excellent agreement with the experimental results of Bidel and coworkers [12], see Fig. 6. These authors probed the CBS cone for a large cloud (\( \sigma = 8098 \)) of scalar optical thickness \( b_0 = 1.93 \) at resonance, and measured an angular width of the cone of 0.50 ± 0.04 mrad. This result is in accord with the theoretical value of 0.46 mrad derived from Eq. (33).

5. Conclusion

We have proposed an iterative multiple scattering approach, where the radiation field at each scattering order is obtained from the field at the atomic positions calculated at the previous order. Provided that all the eigenvalues of the iterative scattering operator have belowunity eigenvalues, it provides a converging solution for the multiple scattering problem. In the opposite case, the picture of waves being scattered at one atom after the other collapses, and the multiple scattering series becomes divergent. A limitation of the approach is that the derivation of the nth scattering order involves \( n - 1 \) integrals over the cloud distribution, which practically limits the efficiency of the method to the first scattering orders for non-trivial geometries.

On the other hand, the series permits us to link observable phenomena to particular scattering orders thus deepening our understanding of their physical origin. As an example, for arbitrary distributions we calculate the double-scattering contributions to backward coherent radiation, the so-called CBS cone.

Finally, the multiple scattering approach presented in this paper may find applications in other many-body scattering problems. One such example is the elucidation of the relationship between Bragg scattering and the phenomenon of photonic bandgaps, the first one occurring in the single and the second one in the multiple scattering regime.

Appendix A: Derivation of Eq. (5)
The radiation field can be obtained from Maxwell equations in the presence of a polarization $\mathbf{P}$. The equations for the Fourier component at the frequency $\omega = c k$ are:

\[
\nabla \times \mathbf{E} = i \omega \mu_0 (\mathbf{c} \mathbf{E} + \mathbf{P}),
\]

\[
\nabla \cdot \mathbf{E} = - (1/\epsilon_0) \nabla \cdot \mathbf{P}.
\]

Taking the curl of Eq. (A1) and using Eq. (A2),

\[
\nabla \times \nabla \times \mathbf{E} = (\omega^2 / c^2) [\mathbf{E} + (1/\epsilon_0) \mathbf{P}],
\]

we obtain

\[
\nabla \times \nabla \times \mathbf{E} = -k^2 \mathbf{E} + \frac{1}{k^2} \nabla (\nabla \cdot \mathbf{P}).
\]

The solution of Eq. (A5) is easily obtained using the scalar Green’s function $G(r) = \exp(ikr)/(ikr)$ as

\[
\mathbf{E}(r) = i \frac{k^3}{4\pi \epsilon_0} \int dr' G(|r - r'|) \left[ \mathbf{P}(r') + \frac{1}{k^2} \nabla (\nabla \cdot \mathbf{P}(r')) \right]
\]

or, for each components,

\[
E_\alpha(r) = i \frac{k^3}{4\pi \epsilon_0} \sum_\beta \int dr' G(|r - r'|) \left[ \delta_{\alpha,\beta} + \frac{1}{k^2} \partial^2 \right] P_\beta(r').
\]

By integrating by parts and using Eq. (3), we derive

\[
E_\alpha(r) = i \frac{k^3}{6\pi \epsilon_0} \sum_\beta \int dr' G_{\alpha,\beta}(r - r') P_\beta(r').
\]

Taking a discrete distribution of electric dipoles with $\mathbf{P}(r) = -d \sum_{j=1}^N b_j \delta(r - r_j)$, we obtain:

\[
\mathbf{E}(r) = -i \frac{dk^3}{6\pi \epsilon_0} \sum_{m=1}^N G(r - r_m) \cdot b_m.
\]

Appendix B: Average over random angular variables for the CBS contribution
Assuming in the double scattering contribution of Eq. (26) $k_0 = k(0, 0, 1)$, $k = k(\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)$ and $\mathbf{r}_{jm} = \mathbf{r}_{jm}(\sin \theta_{jm} \cos \phi_{jm}, \sin \theta_{jm} \sin \phi_{jm}, \cos \theta_{jm})$, where $\mathbf{r}_{jm} = \mathbf{r}_j - \mathbf{r}_m$, then

\[
(k + k_0) \cdot \mathbf{r}_{jm} = kr_{jm}[\sin \theta \sin \theta_{jm} \cos(\phi_{jm} - \phi) + (1 + \cos \theta) \cos \theta_{jm}].
\]

By averaging over $\theta_{jm}$ and $\phi_{jm}$, we obtain

\[
\langle |T_N|_{\text{pairs}} \rangle = \frac{1}{N^2} \sum_{j \neq m} \frac{1}{kr_{jm}^2}
\times \left\{ 1 + \frac{1}{4\pi} \int_0^{2\pi} d\phi_{jm} \int_0^\pi d\theta_{jm} \sin \theta_{jm} \cos \{kr_{jm} \sin \theta \sin \theta_{jm} \cos(\phi_{jm} - \phi) + (1 + \cos \theta) \cos \theta_{jm}\} \right\}.
\]

Using the expression

\[
\frac{1}{2\pi} \int_0^{2\pi} d\phi \cos[a + b \cos(\phi - \phi')] = \cos(a) J_0(b),
\]

the integration over $\phi_{jm}$ gives

\[
\langle |T_N|_{\text{pairs}} \rangle = \frac{1}{N^2} \sum_j \sum_{m \neq j} \frac{1}{kr_{jm}^2}
\left\{ 1 + \frac{1}{2} \int_0^\pi d\theta_{jm} \sin \theta_{jm} \cos \{kr_{jm} (1 + \cos \theta) \cos \theta_{jm}\} J_0[kr_{jm} \sin \theta \sin \theta_{jm}] \right\}.
\]

Using the expression

\[
\int_0^\pi d\theta \sin \theta \cos(\alpha \cos \theta) J_0(b \sin \theta) = \frac{2 \sin \sqrt{a^2 + b^2} - \sqrt{a^2 + b^2}}{\sqrt{a^2 + b^2}} J_0(0),
\]

we obtain

\[
\langle |T_N|_{\text{pairs}}^2 \rangle = \frac{1}{N^2} \sum_j \sum_{m \neq j} \frac{1}{kr_{jm}^2}
\left\{ 1 + \sin[2kr_{jm} \sin(\theta/2)] \right\}.
\]

where $\sin(z) = \sin(z)/z$. 
Appendix C: Derivation of Eq. (30)

Let us consider the integral

\[ I = \int dr_1 \rho(r_1) \int dr_2 \rho(r_2) f(|r_1 - r_2|). \]  

(C1)

Changing integration variables from \( r \) and \( r \) to \( \mathbf{R} = (r_1 + r_2)/2 \) and \( s = r_1 - r_2 \), we obtain

\[ I = \int d\mathbf{R} \int ds \rho(|\mathbf{R} - s/2|) \rho(|\mathbf{R} + s/2|) f(|s|). \]  

(C2)

Assuming a Gaussian distribution, \( \rho(r) = N/(2\pi)^{3/2}\sigma_r^3 \exp(-r^2/2\sigma_r^2) \), since \( |\mathbf{R} + s/2|^2 + |\mathbf{R} - s/2|^2 = 2R^2 + s^2/2 \), the integral (C2) in polar coordinates becomes

\[ I = \frac{2N^2}{\pi \sigma_r^6} \int_0^R dR R^2 e^{-R^2/\sigma_r^2} \int_0^\infty ds s^2 e^{-s^2/4\sigma_r^2} f(s) \]

\[ = \frac{4N^2}{\sqrt{\pi}} \int_0^\infty dx x^2 e^{-x^2} f(2\sigma_r x). \]  

(C3)

Taking

\[ f(s) = \frac{1}{k^2 s^2} \left( 1 + \frac{\sin[2ks \cos(\theta/2)]}{2ks \cos(\theta/2)} \right), \]

the integral is

\[ I = \frac{N^2}{\sigma_r^2 \sqrt{\pi}} \int_0^\infty dx e^{-x^2} \left[ 1 + \frac{\sin(ax)}{ax} \right] \]

\[ = \frac{N^2}{2\sigma_r^2} \left[ 1 + \frac{\sqrt{\pi}}{a} \text{erf}(a/2) \right], \]

where \( \sigma = k\sigma_r \) and \( a = 4\sigma \cos(\theta/2) \).

Appendix D: Derivation of Eq. (32)

Let us consider the coherent contribution \( T_\infty(k, k_0) \) of Eq. (27) and introduce \( \mathbf{R} = (r_1 + r_2)/2 \) and \( s = r_1 - r_2 \), so that

\[ T_\infty(k, k_0) = \frac{1}{i k N} \int d\mathbf{R} \int ds \rho(|\mathbf{R} + s/2|) \rho(|\mathbf{R} - s/2|) s^{-1} e^{i(k_0 - k) \cdot \mathbf{R} + i(k_0 + k) \cdot s/2 + iks}. \]

(D1)

For a Gaussian distribution the double integral factorizes,

\[ T_\infty(k, k_0) = \frac{\rho_0^2}{i k N} \int d\mathbf{R} e^{-R^2/\sigma_r^2 + i(k_0 - k) \cdot \mathbf{R}} \int ds e^{-s^2/4\sigma_r^2 + i(k_0 + k) \cdot s/2 + iks}, \]

(D2)

where \( \rho_0 = N/(2\pi)^{3/2}\sigma_r^3 \). Assuming \( k_0 = k(0, 0, 1) \) and \( k = (\cos \phi, \sin \theta \sin \phi, \cos \phi) \), the first integral yields:

\[ I_1 = \rho_0 \int d\mathbf{R} e^{-R^2/\sigma_r^2 + i(k_0 - k) \cdot \mathbf{R}} = \frac{N}{2\sqrt{2}} e^{-\sigma^2(1 - \cos \theta)/2} \]

(D3)

where \( \sigma = k\sigma_r \). The second integral of Eq. (D2) after integration over the angular variables yields:

\[ I_2 = \frac{2N}{i \sqrt{2\pi}\sigma_r^2 \cos(\theta/2)} \int_0^\infty dx e^{-x^2/4 + iax} \sin[\sigma \cos(\theta/2) x]. \]

(D4)

Using the expression

\[ \int_0^\infty dx e^{-x^2/4 + iax} \sin(ax) = \frac{\sqrt{\pi}}{2} \left\{ -i - e^{4ab} \text{erfi}(a - b) - i + \text{erfi}(a + b) \right\} e^{-(a+b)^2} \]

we obtain, from eqs. (D3) and (D4),

\[ T_\infty(\theta) = \frac{N}{4i\sigma_r^2 \cos(\theta/2)} \left\{ \text{erfi}[\sigma(1 + \cos(\theta/2))] - e^{4\sigma^2 \cos(\theta/2)} \text{erfi}[\sigma(1 - \cos(\theta/2))] + i \left( e^{4\sigma^2 \cos(\theta/2)} - 1 \right) \right\} \]

\[ \times e^{-2\sigma^2(1 + \cos(\theta/2))}. \]

(D5)
Notice that $T_\infty(\pi) = N \exp(-2\sigma^2)$. For large $\sigma$ and near the forward direction, we get:

$$
T_\infty(\theta) \approx \frac{N}{4\sigma^2} e^{-4\sigma^2 \sin^2(\theta/4)} \approx \frac{b_0}{8} e^{-4\sigma^2 \sin^2(\theta/4)}.
$$

(D6)
